A Multithreaded, Transaction-Based Locking Strategy for Containers

Bob Steagall CppCon 2020

Overview

- Sharing a container among multiple threads
- A motivating problem
- Some possible solutions
- A solution based on strict timestamp ordering (STO)
- Testing the STO-based solution
- Summary

Sharing a Container

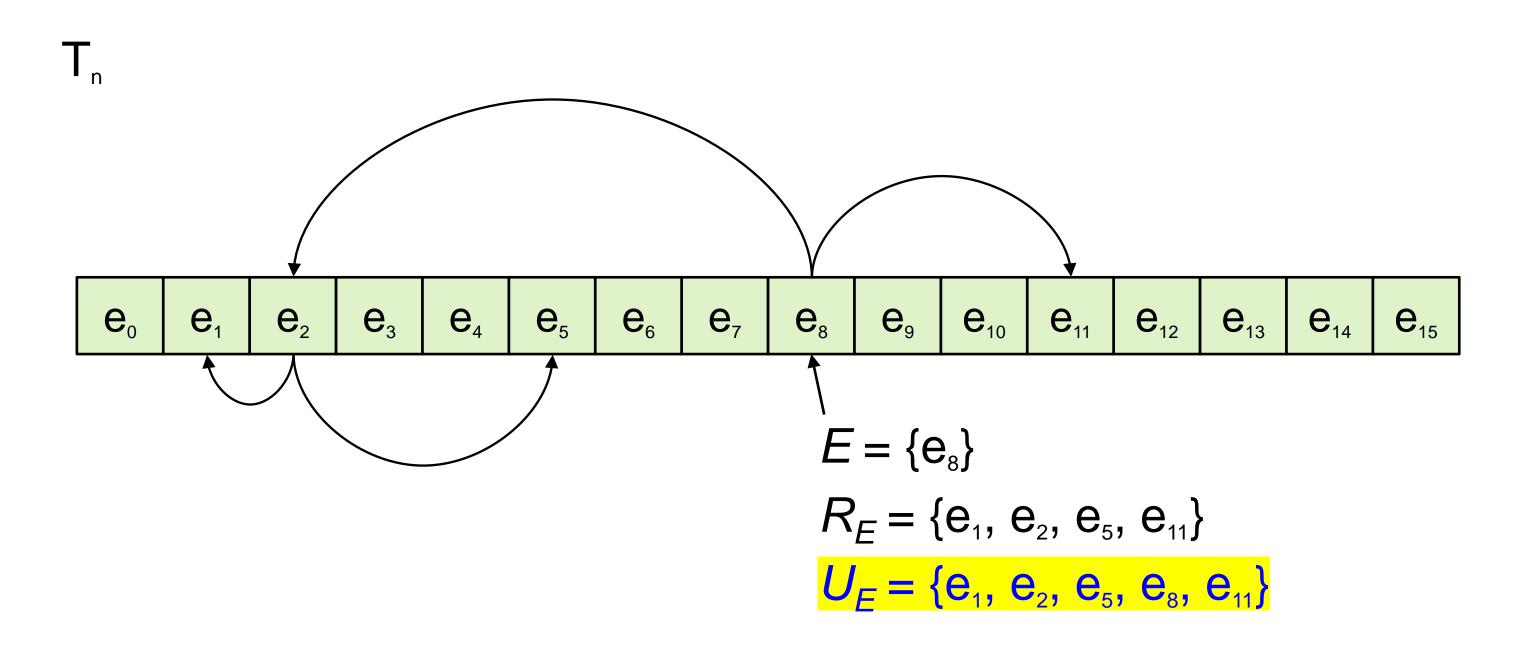

- Sometimes a container must be shared between threads
- We desire to avoid race conditions during writes
 - Assume elements are themselves unsynchronized i.e., susceptible to races
 - Exactly one thread may update an element at any given time
 - No other thread may read an element while the writer is updating it
 - More than one thread may read an element when no update is in progress
- We now have a wealth of concurrency tools at our disposal
 - Writing multi-threaded applications is easier (?) than ever

- If all threads are readers...
 - No locking is required
- If the number of reads is much larger than the number of writes...
 - We might be able to use a readers/writer lock (std::shared_mutex)
- What about the case where most operations are writes?
 - A per-element mutex strategy might work...
 - ... if a given write operation requires locking exactly one element

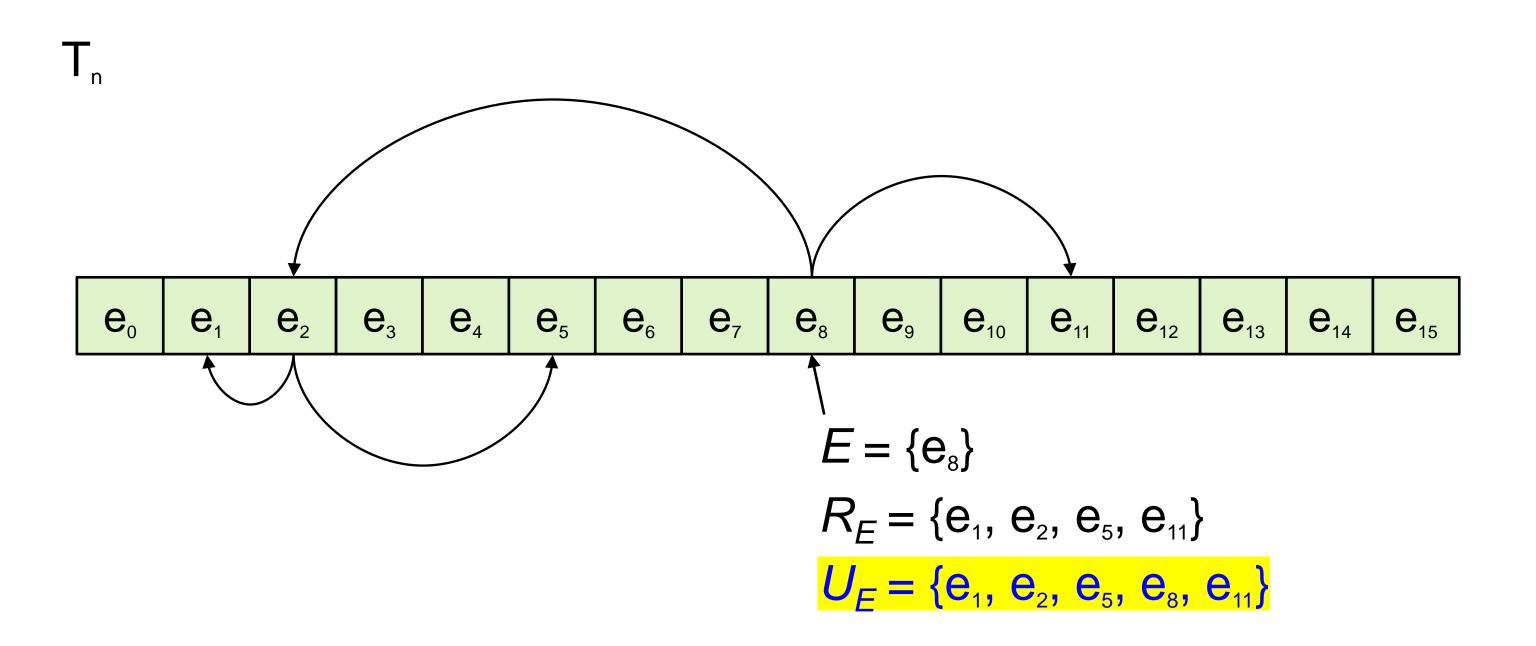

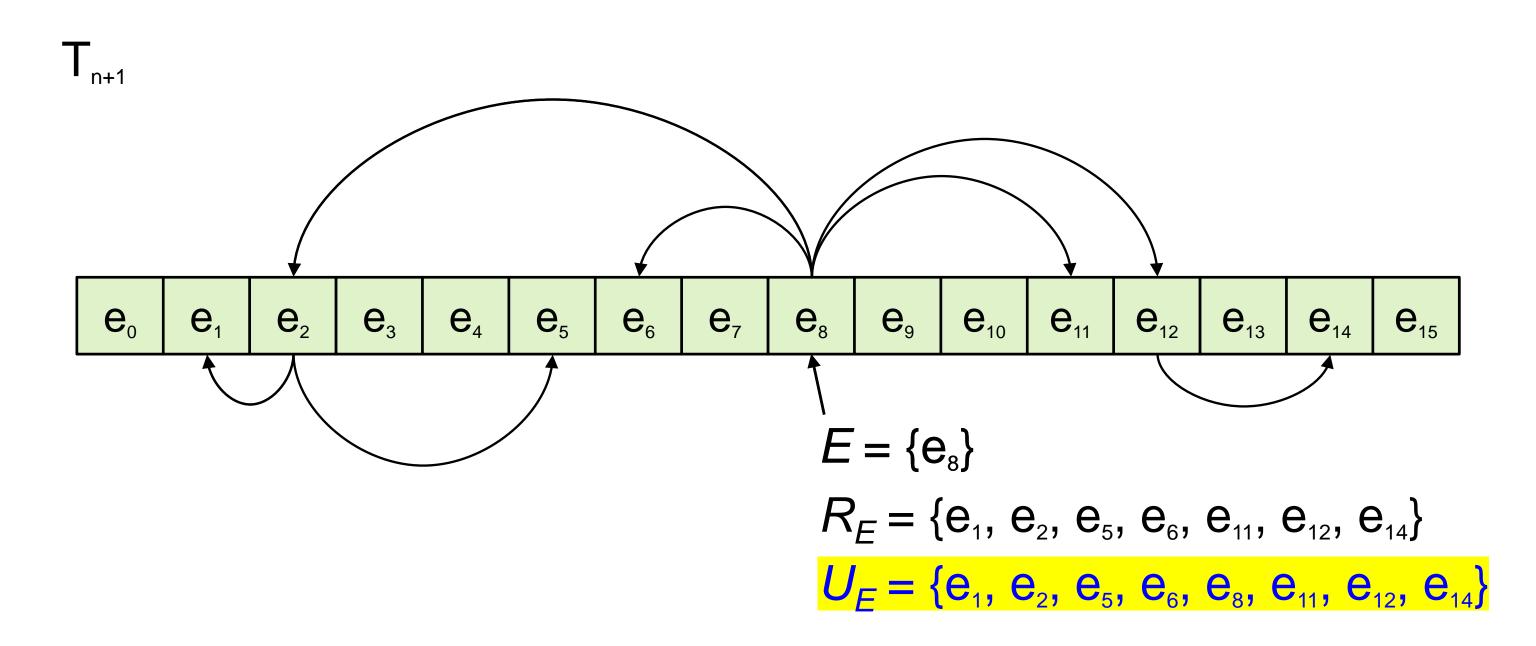

- What about the case where all operations are writes...
 - -- and --
- Each element E to be updated is related to a set R_E of other elements
 - Let's call this set E's related group
 - Let's define $U_E = \{E \cup R_E\}$ and call it E's update group

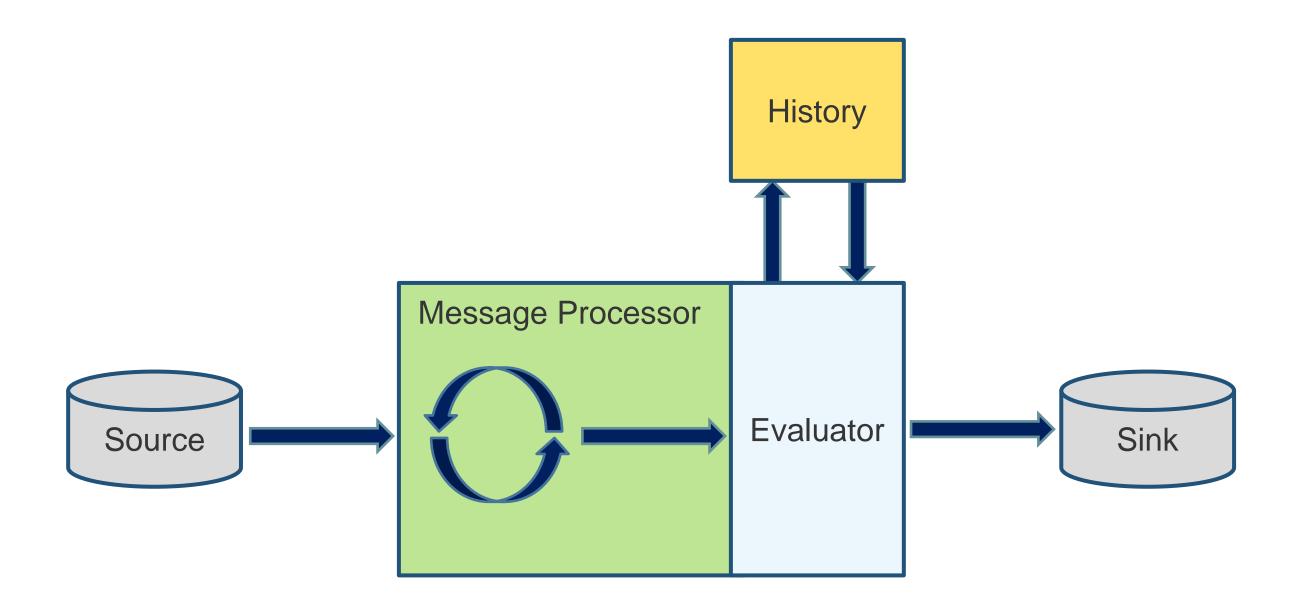

- What about the case where all operations are writes...
 - -- and --
- Each element E to be updated is related to a set R_F of other elements
 - Let's call this set E's related group
 - Let's define $U_F = \{E \cup R_F\}$ and call it *E's update group*
 - -- and --
- One or more elements in $R_{\it E}$ must also be updated at the same time as, and consistently, with $\it E$
 - -- and --
- The number of elements in R_F to be updated varies
 - -- and --
- The membership of R_E varies?

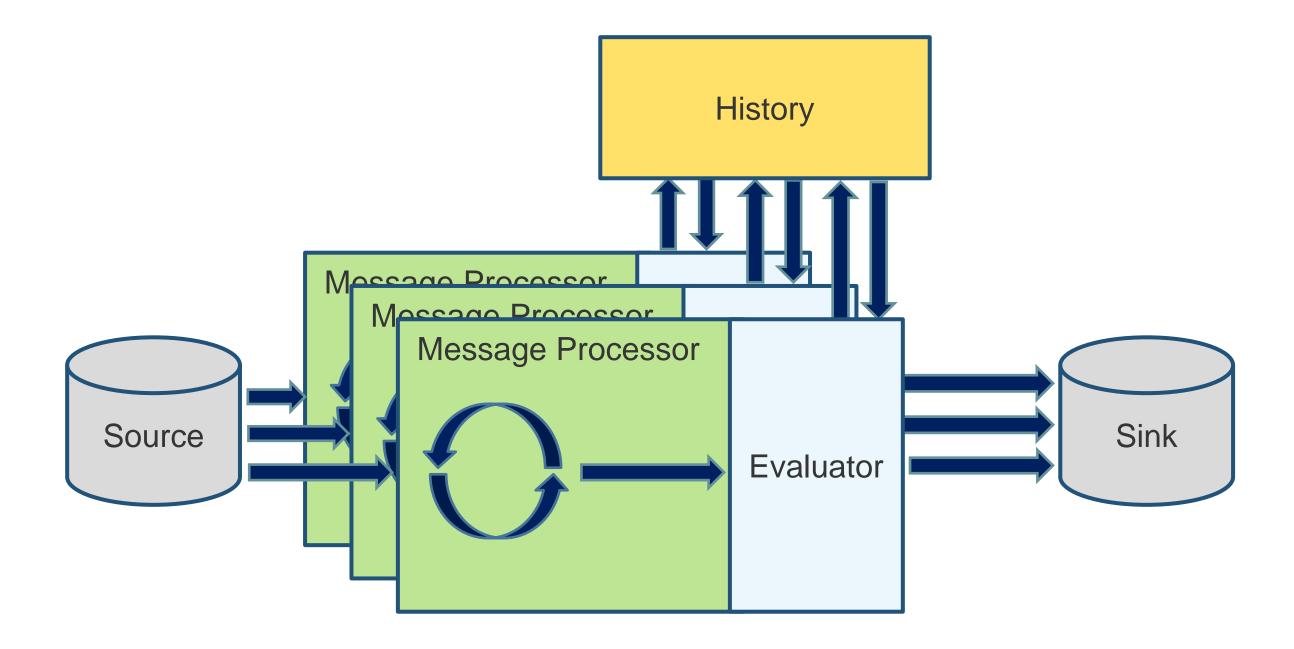

- Receives a continuous stream of input messages
- Generates output only when something interesting happens
 - A history must be maintained to detect relevant changes
- Reading the state of the history is never required
- Every message input requires a write operation to the history
 - Which uses one or more containers

- Receives a continuous stream of input messages
- Generates output only when something special happens
 - History must be maintained to detect "special" changes
- Reading the state of the history is never required
- Every message input requires a write operation to a container
 - Which uses one or more containers
- It must scale to multiple threads!

Solution Requirements

- Atomic: Each modification of an update group is treated as a single transaction, which either succeeds completely, or fails completely
- Consistent: Each transaction can only bring the update group (and the enclosing container) from one valid state to another, maintaining all invariants
- **Isolated**: Each transaction must ensure that concurrent execution of other transactions leaves its update group (and the container) in the same state that would have been obtained as if the transactions were executed in some valid sequential order

Some Solutions – Per-Container Mutex

 Instantiate a per-container mutex and perform updates in a single critical section guarded by the mutex

- Upside
 - It works
 - Easy to understand and think about
- Downside
 - Does not scale

Some Solutions - Sharding

- Divide the set of elements into individual shards such that the members of each element's related group are also in the shard
- Updates to each shard are performed by only one thread dedicated to servicing that shard
- Upside
 - Good performance
- Downside
 - Increased complexity
 - It works IFF the data is amenable to sharding

Some Solutions – Per-Element Mutex

 Instantiate a per-element mutex, acquire the mutexes for all the elements in the update group, then update and release them all

Upside

- Seems like it should work (at least for the case where U_F has exactly one element)
- Slightly more difficult to understand and think about

Downside

- Some mutex implementations are not small
- What if E_0 's related group contains E_1 , and E_1 's related group contains E_0 ?
- Trap!

Some Solutions – Per-Element Mutex

• Instantiate a per-element research text text of all the elements in the update group, then are and release to the second release t

Upside

- Seems like it should work
- Slightly more difficult to understar

Downside

- Some mutex implement of small
- What if E_0 's related group on E_1 , and E_1 's related youp contains E_0 ?
- Trap!

Another Solution – Strict Timestamp Ordering (STO)

- STO is one of many database concurrency control algorithms
- It is a transactional, timestamp-based algorithm

Timestamp

- A monotonically increasing value that indicates the age of a transaction
- A lower timestamp value (TSV) indicates an older transaction
- A higher timestamp value indicates a newer transaction
- A transaction's TSV is its "birthday"
- STO uses timestamps to serialize concurrent transactions

Strict Timestamp Ordering

- When each transaction begins it is assigned a unique timestamp from an authoritative, universal timestamp source
- If two transactions are attempting to write the same update group at the same time, the transaction with the lower timestamp goes first
 - Younger transactions always wait for older transactions
 - Older transactions never wait for younger transactions, they give up (roll back) and try again
- STO operation schedules are serializable and deadlock-free
 - Price for deadlock-freedom is the potential restart of a transaction

Strict Timestamp Ordering – General Case

- An element E with
 - A read timestamp rd_tsv
 - A write timestamp wr_tsv
- A transaction TX₁ with timestamp tsv
 - Functions begin(), commit(), and rollback()
 - Facility for TX₁ to "acquire" E
- Function update() to update E
- Function read() to read from E

Strict Timestamp Ordering – General Case

Transaction TX₁ calls read(E)

- If [TX₁.tsv < E.wr_tsv] then
 - A younger transaction (TX₂) has already written E, so call rollback(TX₁)
- If [TX₁.tsv > E_n.wr_tsv] then
 - An older transaction (TX₀) is in progress involving E
 - TX₁ waits until all older transactions (i.e., TX₀) are complete
 - TX₁ acquires E, assigns TX₁.tsv to E.rd_tsv, and reads E's contents

Strict Timestamp Ordering – General Case

Transaction TX₁ calls update(E)

- If [TX₁.tsv < E.rd_tsv] then
 - A younger transaction (TX₂) has already read from E, so call rollback (TX₁)
- If [TX₁.tsv < E.wr_tsv] then
 - A younger transaction (TX₂) has already written to E, so call rollback (TX₁)
- If $[TX1.tsv > E_n.wr_tsv]$ then
 - An older transaction (TX₀) is in progress involving E
 - TX₁ waits until all older transactions (i.e., TX₀) are complete
 - TX₁ acquires E, assigns TX₁.tsv to E.wr_tsv, and updates E's contents

Implementing STO in C++

- For our problem, we assume all operations are updates
 - Then we need only one timestamp per element, E.tsv

Transaction TX₁ calls update(E)

- If [TX₁.tsv < E.tsv] then
 - A younger transaction (TX₂) has already written to E, so call rollback (TX₁)
- If [TX₁.tsv > E.tsv] then
 - An older transaction (TX₀) is in progress involving E
 - TX₁ waits until all older transactions (i.e., TX₀) are complete
 - TX₁ acquires E, assigns TX₁.tsv to E.tsv, and updates E's contents

- Need some basic synchronization components
 - Mutex
 - Condition variable
 - Atomic pointer
 - Atomic compare and exchange
- Need a class that represents a lockable item (element)
- Need a class that manages transactions on behalf of each thread
 - Transactions are represented by a timestamp value (TSV)

- Threads share containers holding lockable items
- Threads will initiate transactions, and each thread owns its transactions
- A transaction's key operations (begin, acquire, commit, rollback) can only be performed by the owning thread
- A transaction manger acquires lockable items on behalf of its owning thread
 - Other logic in the owning thread performs actual update operations
- In a transaction, the entire update group must be acquired before the thread applies any write operation to any member of that group

```
thread function(shared_collection)
    [Create a transaction manager]
    while [Work remains to be done]
        [Begin a new transaction]
        [Find target element E in shared_collection]
        [Determine the membership of the update group to the extent possible]
        while [Update group members remain unacquired AND acquisitions have all succeeded]
            [Starting with E, attempt to acquire the next unacquired member of the update group]
            [Revise the membership of the update group, if necessary]
        endwhile
        if [All members of the update group were acquired]
            [Apply write operations to the members of the update group]
            [Commit the transaction, loop back to the top, get new work]
        else
            [Roll back the transaction, loop back to the top, and try again]
        endif
    endwhile
```

```
thread function(shared_collection)
    [Create a transaction manager]
    while [Work remains to be done]
        [Begin a new transaction]
        [Find target element E in shared_collection]
        [Determine the membership of the update group to the extent possible]
        while [Update group members remain unacquired AND acquisitions have all succeeded]
            [Starting with E, attempt to acquire the next unacquired member of the update group]
            [Revise the membership of the update group, if necessary]
        endwhile
        if [All members of the update group were acquired]
            [Apply write operations to the members of the update group]
            [Commit the transaction, loop back to the top, get new work]
        else

Atomic Compare and Exchange

- Paraphrasing cppreference.com:
 - Atomically compares the representation of *this with that of expected, and if those are bitwise-equal, replaces the representation of *this with desired and returns true;
 - Otherwise, loads the actual value stored in *this into expected and returns false.

            return true;
        else
            return false;
    else
```

Testing

Test Strategy

- Create functions to update a collection of shared items
 - Make sure that data races are possible and can be detected
- Measure single-threaded updates baseline
- Measure multi-threaded updates with induced data races
- Measure multi-threaded updates guarded by a single critical section
- Measure multi-threaded transactional updates
- 8-Core (16 hypercores), Ubuntu 18.04, GCC 10.2

Testing – Includes, etc.

```
#include "transaction.hpp"
using namespace tx;
using namespace std;
using namespace std::chrono_literals;
//- Forward declarations and common type aliases common to the test functions below().
struct test item;
using item list = std::vector<test item>;
using index list = std::vector<size t>;
using entropy = random device;
using prn gen = mt19937 64;
using int dist = uniform int distribution<>;
using hasher = hash<string view>;
```

Testing - test_item

```
//- Updates on-board data for the non-STO tests. Checks to see if a race has occurred.
void
test_item::st_update(FILE* fp, prn_gen& gen, int_dist& char_dist)
                   local chars[buf size];
    char
    string view
                   local_view(local_chars, buf_size);
    string view
                   shared view(ma chars, buf size);
   hasher
                   hash;
   for (size t i = 0; i < buf size; ++i)
        local_chars[i] = ma_chars[i] = (char) char_dist(gen);
    if (hash(shared_view) != hash(local_view))
        fprintf(fp, "RACE FOUND!, item %zd\n", this->id());
```

```
//- Updates on-board data for the non-STO tests. Checks to see if a race has occurred.
void

```

Test Results

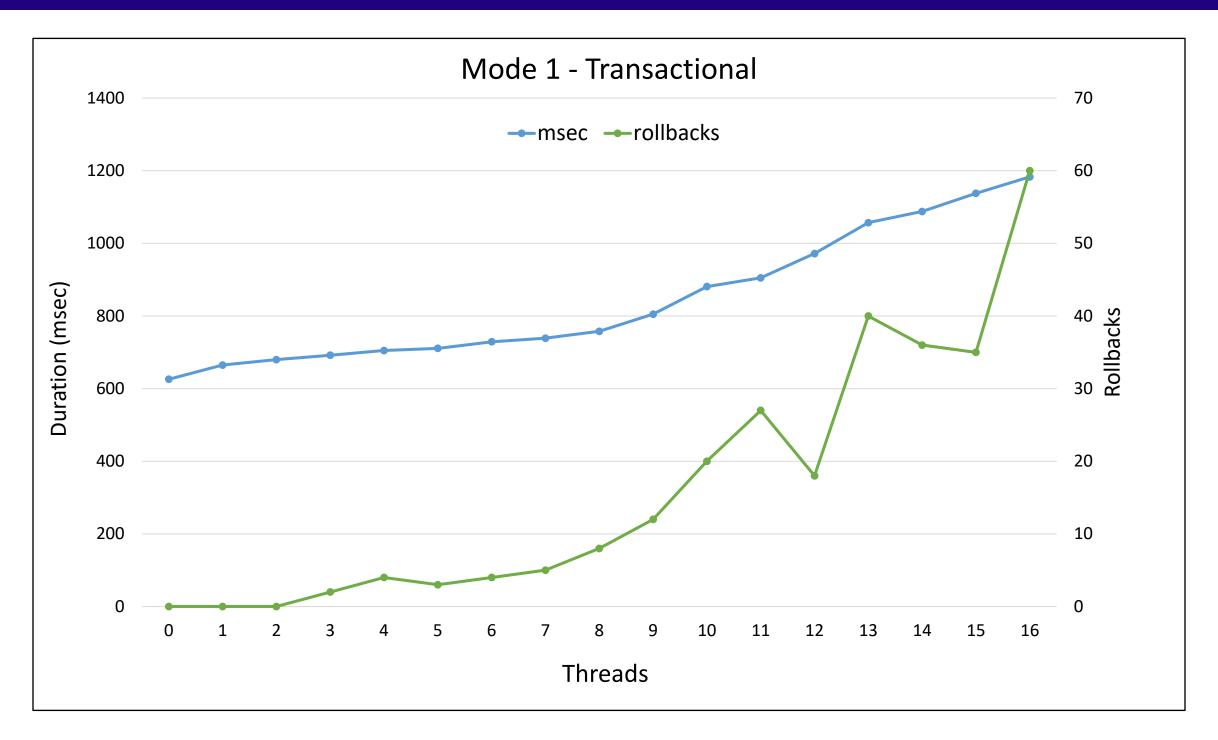

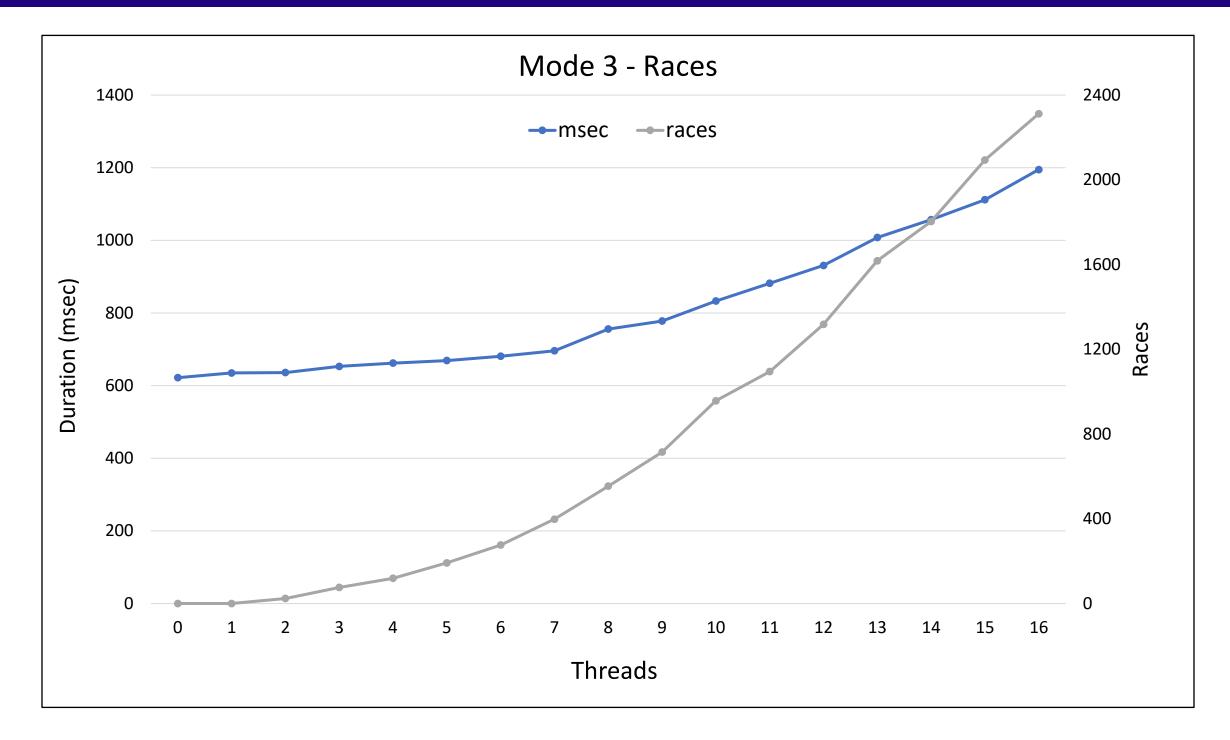

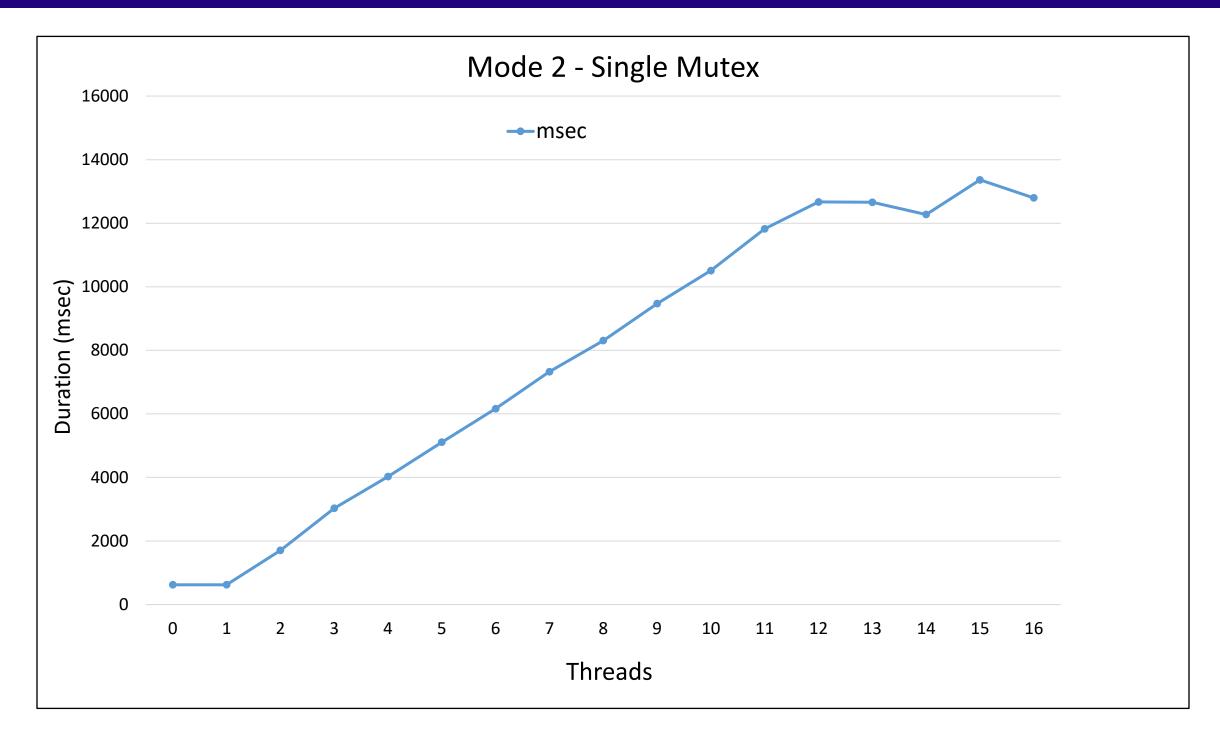

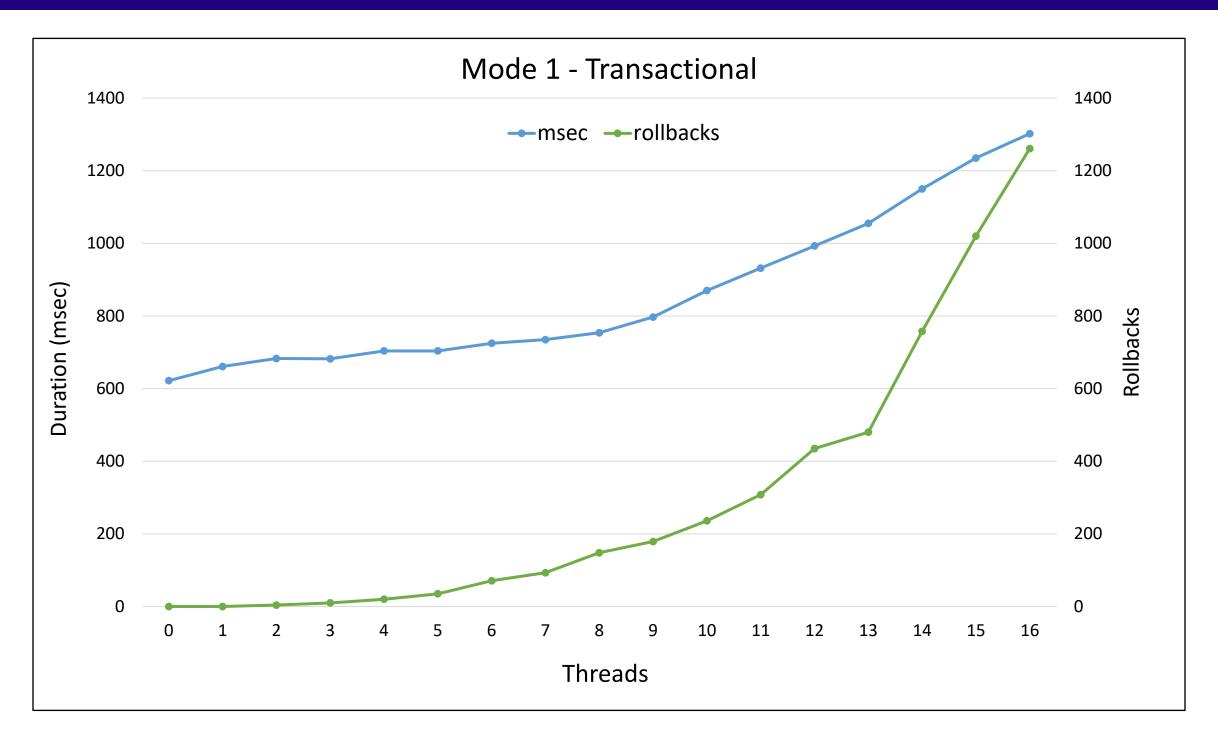

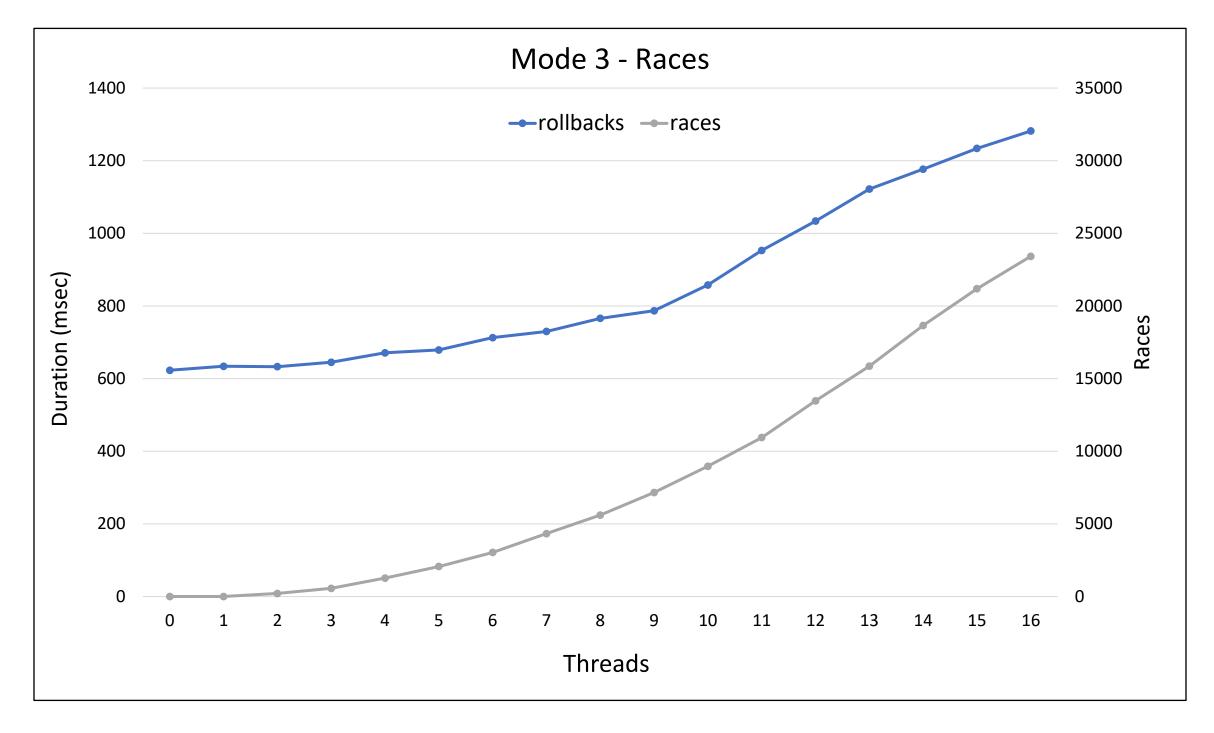

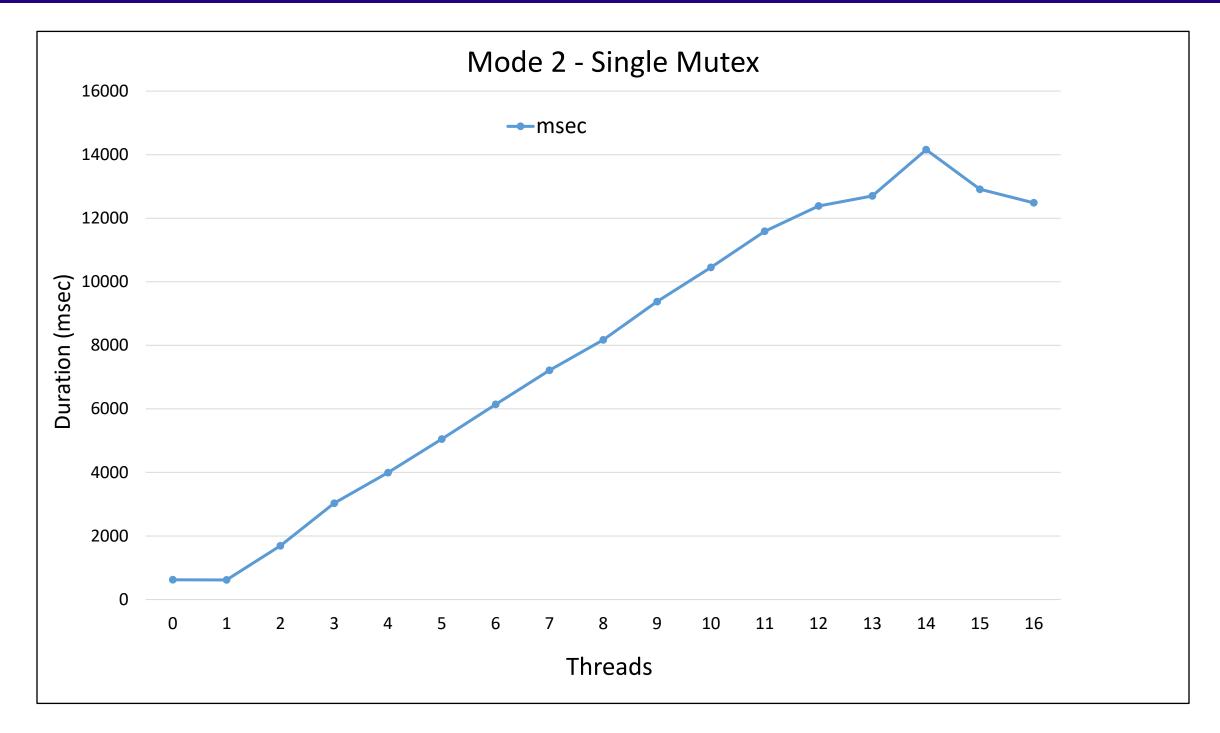

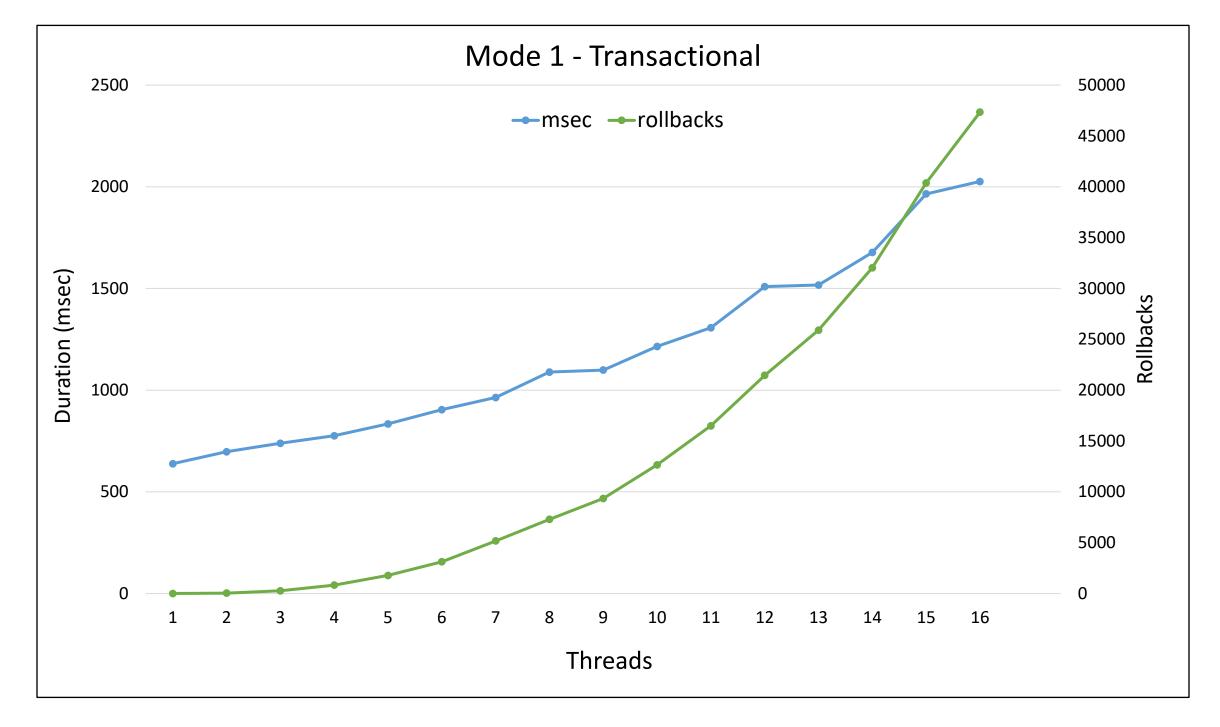

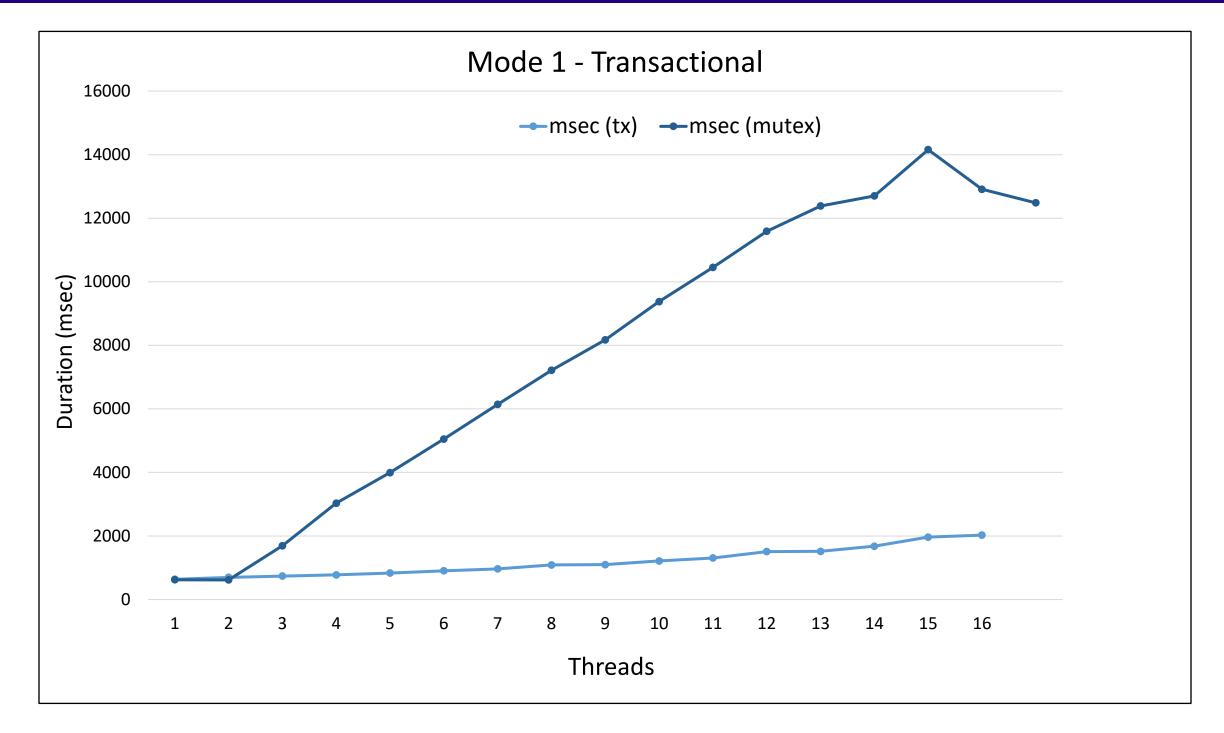

Summary

Some Comments

- These tools operate upon containers and with elements, but don't require changing the containers themselves
- There is an assumption that the container's internal structure is unchanged while transactions are in progress
 - Consider the case of a vector resize
 - Consider the case of adding an element to a map
 - Could this be handled by a per-container shared mutex?

Some Comments

- So far, only std::vector has been used
 - The maximum number of elements is pre-allocated and resizes don't occur
- To obtain a container that is resizable
 - Create a home-grown hash table using std::vector
 - Each element of the vector is a hash bucket
 - Hash buckets have member functions for adding, finding, erasing elements
 - Hash buckets are locked during transactions, and their contents updated
 - With a good hash function, lookup time is quite fast (but not as fast as indexing)

Some Comments

- Some threads could starve
 - Transactions might become stale
- Other container types may be amenable...?
- Lots of room for more work

Thank You for Attending!
